RESEARCH LETTER

10.1029/2024GL112835

Key Points:

- We train a neural network to learn a low-dimensional representation of sea surface height that facilitates regional predictions
- The approach can work well in situations where linear inverse models struggle, such as on daily-averaged data
- Reconstruction skill highlights sources of predictability, such as the low-latitudes for North Pacific daily sea surface heights

Abstract Due to the wide range of processes impacting the sea surface height (SSH) on daily-to-interannual timescales, SSH forecasts are hampered by numerous sources of uncertainty. While statistical-dynamical methods like Linear Inverse Modeling have been successful at making forecasts, they often rely on assumptions that can be hard to satisfy given the nonlinear dynamics of the climate. Here, we train convolutional autoencoders with a dynamical propagator in the latent space to generate forecasts of SSH anomalies. Learning a nonlinear dimensionality reduction and the prediction timestepping together results in a propagator that produces better predictions for daily- and monthly-averaged SSH in the North Pacific and Atlantic than if the dimensionality reduction and dynamics are learned separately. The reconstruction skill of the model highlights regions in which better representation results in improved predictions: in particular, the tropics for North Pacific daily SSH predictions and the Caribbean Current for the North Atlantic.

Plain Language Summary Forecasts of sea surface heights are impacted by numerous sources of uncertainty. While statistical methods for representing temporal changes in the climate system have been useful for making predictions, they often rely on assumptions that do not always hold due to the complex interactions in the climate system. Here, we make a machine learning model that learns a compressed representation of the climate system which facilitates sea surface height predictions. The learned compressed representation of the climate system results in better sea surface height predictions than would occur if the dimensionality reduction and prediction is done separately. Our machine learning model also points to regions where more accurately representing sea level can result in better regional-scale predictions.

1. Introduction

The large variety of processes impacting sea surface heights (SSH) on daily-to-interannual timescales implies that forecasts of SSH on these time horizons are hindered by numerous sources of uncertainty. SSH variability on these timescales is driven by factors including barotropic adjustment to wind stress (Hermans et al., 2022; Kamp et al., 2024; Vinogradova et al., 2007), air-sea buoyancy fluxes (Cabanes et al., 2006; Gill & Niller, 1973), wind-driven Ekman pumping (Cabanes et al., 2006; Webb, 2021), changes in large-scale Sverdrup balance (Cabanes et al., 2006), advection of density anomalies (Piecuch & Ponte, 2011), Rossby waves (Calafat et al., 2018; Chelton & Schlax, 1996), buoyancy-driven changes in ocean circulation (Roberts et al., 2016), eddy variability due to baroclinic instability (Marques et al., 2022), and atmospheric pressure anomalies (Piecuch et al., 2016). Developing forecasts for SSH amid these numerous drivers thus presents a challenge.

Over the past few decades, statistical-dynamical methods have proven effective for developing forecasts directly from data. Forecasts generated using Linear Inverse Models (LIM, Penland (1989), Penland and Sardeshmukh (1995)) have had substantial success in predicting the large-scale evolution of geophysical fields on these timescales (Albers & Newman, 2021; Fraser et al., 2019; Newman, Shin, & Alexander, 2011; Zanna, 2012). The framework generally involves first applying dimensionality reduction to represent the system state using a low-dimensional embedding, and then determining a linear propagator from time-lagged covariance statistics. The premise of this approach is that the state evolution can be represented as the sum of slow, predictable, linear dynamics and fast, unpredictable, nonlinear dynamics modeled by Gaussian noise (Hasselmann, 1976). Despite their simplicity, LIMs have demonstrated skill comparable to operational forecasting models in some cases (Albers & Newman, 2021; Richter et al., 2020; Shin & Newman, 2021).

One appealing aspect of LIMs is the simplified representation of the dynamics as a low-dimensional, linear propagator. While nonlinear dynamical systems can be chaotic, unpredictable, and nontrivial to solve, linear

dynamical systems readily admit closed-form solutions and can be solved systematically. The eigenvalues of the propagator can be used to identify dominant timescales for the dynamics of the system as well as optimal initial conditions for producing anomaly growth (Penland & Sardeshmukh, 1995; von Storch et al., 1995; Vimont et al., 2014; Zanna, 2012). However, ensuring that the state evolution is plausibly described by a linear stochastic dynamical system is often challenging, as it depends on the processes being represented and the temporal resolution of the data. The computed propagator typically depends on the time lag used to compute it, due to nonstationary statistics (Penland & Sardeshmukh, 1995), unrepresented processes (Penland & Ghil, 1993), fundamental deficiencies in representing dynamical systems using Markov models (DelSole, 2000), and sampling of intrinsic oscillatory modes of the system (Penland, 2019).

Another sensitivity lies in the application of dimensionality reduction. Clearly, the number of dimensions used to represent the state is a parameter (Newman, Alexander, & Scott, 2011). Additionally, the performance of a LIM may depend on the dimensionality reduction technique applied. Typically, Principal Component Analysis (PCA), also known as Empirical Orthogonal Function analysis, is used to reduce the dimensionality of the system (Hotelling, 1933; Lorenz, 1956; Pearson, 1901). However, the requirement that modes are orthogonal can be restrictive (Dommegård & Latif, 2002). Neural network autoencoders can relax the assumptions of linearity and orthogonality to obtain more efficient low-dimensional embeddings (Hinton & Salakhutdinov, 2006; Kramer, 1991). Nevertheless, it is unclear whether a more efficient yet complex representation will result in better predictions.

Complementing the linear-stochastic dynamical systems framework in inverse modeling of the earth system is the burgeoning set of data-driven approaches based on the operator-theoretic perspective of nonlinear dynamics. Under Koopman operator theory, nonlinear dynamical systems are represented through the linear (but infinite-dimensional) Koopman operator, which temporally advances measurements of the system (Koopman, 1931). Thus, obtaining low-dimensional representations of the Koopman operator is a key goal of data-driven dynamical systems modeling. For instance, Dynamic Mode Decomposition seeks to find the best-fit linear model that advances linear measurements of the system (Schmid, 2010); however, such linear measurements may be insufficient to capture the complexities of nonlinear systems. Therefore, recent deep-learning approaches have modified the autoencoder architecture to learn nonlinear transformations into latent spaces in which the dynamics are approximately linear (Brunton & Kutz, 2022; Champion et al., 2019; Lusch et al., 2018; Mardt et al., 2018; Yeung et al., 2019).

Here, we leverage the Koopman Autoencoder framework in Lusch et al. (2018) to construct a linear propagator for SSH prediction on daily-to-interannual timescales in the North Pacific and North Atlantic. We assess forecasts made by this model relative to baselines in which the dimensionality reduction and propagator are learned separately. We examine the areas of reconstruction skill to interpret how the Koopman Autoencoder attains its performance.

2. Methods

2.1. Data

We use daily- and monthly-averaged simulated SSH fields from the Community Earth System Model, version 2 (CESM2) Large Ensemble data set (LENS2, Rodgers et al. (2021), Danabasoglu et al. (2021)). The data is from the 250-year simulation period spanning 1850–2100, with radiative forcing following the historical record from 1850 to 2014 and the CMIP6 SSP3–7.0 forcing scenario thereafter (Danabasoglu et al., 2020; O'Neill et al., 2016). Fields are detrended using a locally-fitted fifth-degree polynomial and deseasonalized by removing climatological daily averages.

Sea surface heights η are computed by

$$\eta(x, y, t) = \zeta(x, y, t) + \eta_{\text{ib}}(x, y, t) \quad (1)$$

where ζ is the dynamic sea level simulated by CESM2 and η_{ib} is the inverse barometer contribution to sea level (Gregory et al., 2019; Ponte, 2006), given by

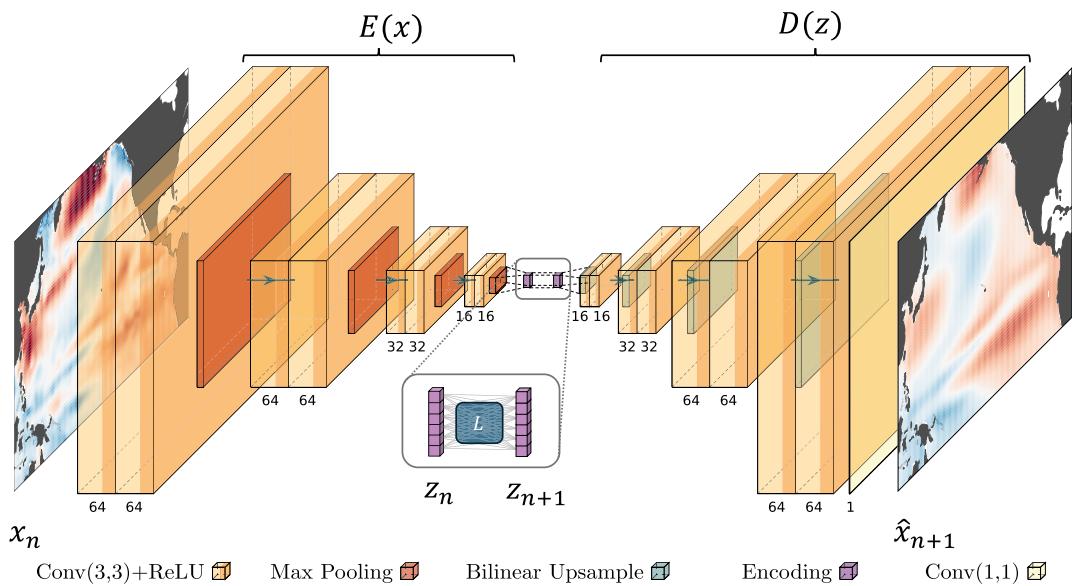

Figure 1. Koopman Autoencoder schematic. The encoder and decoder are denoted by the brackets labeled $E(x)$ and $D(z)$, respectively, and the inset shows the linear propagator. Yellow blocks indicate convolutional layers, and orange shading indicates ReLU activations. Red and green blocks indicate pooling and upsampling layers, respectively.

$$\eta_{\text{ib}}(x, y, t) = -\frac{1}{\rho_0 g} p'_d(x, y, t). \quad (2)$$

Here, $p'_d(x, y, t) = p_a(x, y, t) - \frac{1}{A} \int_A p_a(x, y, t) dA$ is the sea level pressure deviation from the spatial average over the ocean area A at time t , $\rho_0 = 1025 \text{ kg m}^{-3}$ is the reference sea surface density (Fofonoff & Millard, 1983; Smith et al., 2010), and $g = 9.81 \text{ m s}^{-1}$ is the acceleration due to gravity.

We use nine ensemble members, with seven members for training and one member for validation and testing. We focus on two regions: the North Pacific (15°S – 60°N , 115°E – 60°W) and the North Atlantic (5° – 65°N , 60°W – 0°E). For training, fields are standardized using the area-weighted mean and standard deviation averaged over all training samples (LeCun et al., 2002). Land points are masked with zeros.

2.2. Koopman Autoencoder

Figure 1 illustrates the Koopman Autoencoder, which is inspired by Lusch et al. (2018). The network functions as a propagator for a dynamical system with the entire SSH field as its state variable: it consumes input fields of SSH at a given timestep n (x_n) and outputs the predicted SSH field at the next timestep (\hat{x}_{n+1}). We use a timestep of one day for networks trained on daily averages and one month for networks trained on monthly averages.

We employ a convolutional architecture well-suited for the spatial fields comprising our system state (Fukushima, 1980; LeCun et al., 1989). The encoder E takes in the state vector x_n , extracts features using convolutional filters and transforms the inputs to a lower dimensional embedding z_n . Then, a linear layer L is applied to the latent embedding, functioning as a single propagation timestep. Finally, the decoder D transforms the encoded prediction back into the state space, using the state at the next timestep x_{n+1} as the target.

During training, parameters in the Koopman Autoencoder are adjusted through backpropagation (Rumelhart et al., 1986) to optimize a combination of different objective functions in accordance with Lusch et al. (2018):

1. The reconstruction error

$$\mathcal{L}_{\text{reconst}}(x_n) = \|x_n - D(E(x_n))\|_{2,w}^2, \quad (3)$$

where $\|\cdot\|_{2,w}$ is the area-weighted ℓ^2 -norm (see Text S2 in Supporting Information S1). This loss ensures that the encoder and decoder learns a maximally-efficient representation of the SSH in the d -dimensional latent space.

2. The prediction error

$$\mathcal{L}_{\text{pred}}(x_n, \dots, x_{n+k}) = \frac{1}{k} \sum_{\ell=1}^k \|x_{n+\ell} - D(L^\ell E(x_n))\|_{2,w}^2. \quad (4)$$

The norm $\|x_{n+1} - D(L E(x_n))\|_{2,w}^2$ indicates the prediction error incurred during a single propagation timestep. In practice, better predictions are obtained by penalizing ℓ -timestep predictions for $\ell \in \{1, \dots, k\}$, where the ℓ -timestep prediction $\hat{x}_{n+\ell}$ is given by ℓ applications of the propagator L to the latent embedding: $\hat{x}_{n+\ell} = D(L^\ell E(x_n))$. In order to balance prediction performance with computational feasibility, we use $k = 20$ recurrent passes for all networks (see Text S1 in Supporting Information S1).

We also add a latent space prediction error

$$\mathcal{L}_{\text{linear}}(x_n, x_{n+1}) = \|LE(x_n) - E(x_{n+1})\|_2^2 \quad (5)$$

which further ensures that the linear prediction $\hat{z}_{n+1} = L z_n = LE(x_n)$ approximates the latent state at the next timestep $z_{n+1} = E(x_{n+1})$. This term may be redundant as our propagator L is not equipped with activations, but is added for consistency with the methodology of Lusch et al. (2018).

The net loss is given by

$$\mathcal{L}(x_n, \dots, x_{n+k}) = \lambda_1 \mathcal{L}_{\text{reconst}}(x_n) + \lambda_2 \mathcal{L}_{\text{pred}}(x_n, \dots, x_{n+k}) + \lambda_3 \mathcal{L}_{\text{linear}}(x_n, x_{n+1}) \quad (6)$$

where λ_1 , λ_2 , and λ_3 are hyperparameters. By optimizing this loss, the dimensionality reduction and the time-stepping are learned together. Thus, the dimensionality reduction is constructed in such a way that predictions are improved.

Separate networks are trained for each region and timescale. Full details about the data preparation, network architecture, and training procedure are given in Text S1 in Supporting Information S1.

2.3. Baselines

We contrast the predictions made with our Koopman Autoencoders with baselines in which the dimensionality reduction and predictions are done separately. For dimensionality reduction, we consider Principal Component Analysis (PCA) and Convolutional Autoencoders (CAE). For forecasting, we apply Damped Persistence (DP) and Linear Inverse Modeling (LIM). Prediction baselines are thus determined by combining the two techniques, and are denoted according to the dimensionality reduction and propagator used, for example, “PCA-LIM” or “CAE-DP.”

2.3.1. Dimensionality Reduction Techniques

As a first baseline, PCA is applied to reduce the dimensionality of the state. In PCA, the data is linearly projected onto the d -dimensional subspace that maximizes the variance of the data. Therefore, dimensions describing the data are linear and orthogonal, a restriction that may result in poor representation of nonlinear data manifolds.

As a nonlinear alternative, we also train Convolutional Autoencoders (CAE). Autoencoders generalize PCA by allowing for nonlinear transformations to a latent space and can learn more efficient representations than PCA (Hinton & Salakhutdinov, 2006; Kramer, 1991; Oommen et al., 2022; Shamekh et al., 2023). For the CAE, we use an encoder and decoder with the same architectures as those of the Koopman Autoencoder, and we train it with nearly identical hyperparameters (see Text S1 in Supporting Information S1).

2.3.2. Latent Space Timestepping

We compare forecasts made by the Koopman Autoencoder to Damped Persistence (DP, Lorenz (1973)). Given a latent state z_n , the prediction at lag τ is given by

$$\hat{z}_{n+\tau} = \mathbf{D}(\tau)z_n \quad (7)$$

where $\mathbf{D}(\tau)$ is a diagonal matrix whose entries give the autocorrelation of each of the latent variables at lag τ . The propagator $\mathbf{D}(\tau)$ is computed iteratively for each time lag by first selecting a training timescale τ_0 , computing the lag- τ_0 autocorrelations $\mathbf{D}_0 = \mathbf{D}(\tau_0)$, and then defining $\mathbf{D}(\tau) = (\mathbf{D}_0)^{\tau/\tau_0}$. For a fair comparison with the Koopman Autoencoder, we set τ_0 by fitting DP models using $\tau_0 \in \{1, \dots, k\}$ and selecting the model with the lowest average prediction error on timesteps 1 to k on the validation data set.

We also explore predictions made by a Linear Inverse Model (LIM, Penland (1989)). The underlying assumption behind LIM is that the dynamics of a system can be well-represented as a linear dynamical system forced by noise:

$$\frac{dz}{dt} = \mathbf{A}z + \xi \quad (8)$$

where ξ is normally-distributed white noise. Then, the evolution matrix \mathbf{A} can be estimated through an error minimization procedure as

$$\mathbf{A} = \frac{1}{\tau_0} \log(\mathbf{C}(\tau_0) \mathbf{C}(0)^{-1}) \quad (9)$$

where $\mathbf{C}(\tau) = \langle z(t + \tau)z^T(t) \rangle$ gives the time- τ lagged covariance (with angled brackets denoting a time average) and τ_0 is a fitted timescale. Predictions are then given by

$$\hat{z}_{n+\tau} = \mathbf{B}(\tau)z_n \quad (10)$$

with

$$\mathbf{B}(\tau) = \exp(\mathbf{A}\tau) = \exp\left[\frac{\tau}{\tau_0} \log(\mathbf{C}(\tau_0) \mathbf{C}(0)^{-1})\right]. \quad (11)$$

The covariance matrix is computed over all ensemble members, and again τ_0 is selected by fitting LIMs for $\tau_0 \in \{1, \dots, k\}$ and selecting the model with the lowest error over timesteps 1 through k .

In order for a LIM to be valid, several conditions should be met. One basic criterion is that the learned propagator should be stable with decaying eigenvalues. (Similarly, eigenvalues of the propagator learned by the Koopman Autoencoder should also decay). Figure S1 in Supporting Information S1 verifies that all propagators considered in this study are stable. Another requirement is that the evolution matrix defined by Equation 9 must be independent of the time lag τ_0 used to compute it. This is a strong criterion to meet; common practice is to compute the evolution matrix norm $\|\mathbf{A}\|_2$ for different τ_0 and to select a propagator based on a timescale τ_0 in which the matrix norm is relatively constant. Figure S2 in Supporting Information S1 shows the ℓ^2 -matrix norms of the evolution matrix of the LIM baselines on the range $\tau_0 \in \{1, \dots, k\}$; over this range, the matrix norm varies by over 300% for all of the regions and timescales considered.

3. Results

In this section, we compare the forecasts made by the Koopman Autoencoder to the baselines. Predictions are assessed using the Mean Square Error (MSE), Pattern Correlation Coefficient (Legates & Davis, 1997), and MSE-based skill scores (Murphy, 1988). Metrics are defined explicitly in Text S2 in Supporting Information S1.

3.1. Evaluating Prediction Performance

Figure 2 compares the area-weighted prediction MSE and pattern correlation of SSH predictions of the Koopman Autoencoder to the baselines using $d = 20$ latent dimensions on forecast leads up to $\tau_{\max} = 120$ days (daily data) and $\tau_{\max} = 36$ months (monthly data). The CAE generally has the lowest reconstruction error for all dimensionality reduction techniques, beating PCA MSE by a margin of 2%–4% at lead $\tau = 0$ for all regions and timescales except in the North Atlantic on monthly data (See Table S1 in Supporting Information S1). The Koopman Autoencoder has the worst reconstructions of all the methods: over all regions and timescales, MSE is on average 32% higher for the Koopman Autoencoder than for PCA. Although the Koopman Autoencoder has an encoder and decoder with identical architectures as those of the CAE, the inclusion of additional loss functions for prediction and linearity during training creates competing objectives that result in less efficient reconstructions.

However, the better reconstruction error of the CAE does not necessarily result in better predictions. In fact, predictions made by applying propagators to CAE modes are often worse than predictions made using PCA for dimensionality reduction (e.g., using a DP propagator for North Pacific daily SSH, Figure 2a). In contrast, the Koopman Autoencoder generally results in better predictions than the baselines as measured by the area-weighted MSE and pattern correlation. Predictions from all models devolve to climatological errors as forecast leads increase (indicating the loss of predictability in the system) but errors generally grow most slowly for the Koopman Autoencoder. Table S2 in Supporting Information S1 quantitatively summarizes the forecast performance of the models in Figure 2 through the skill score of the different prediction methods relative to PCA-DP, averaged over forecast leads up to τ_{\max} . Skill of the models relative to PCA-DP depends significantly on the region and timescales considered but averaged over all regions and timescales, PCA-LIM has about 6.8% skill over PCA-DP, skill of CAE-LIM is slightly *worse* than PCA-LIM (6.4%), and skill of the Koopman Autoencoder is the highest (8.4%). In effect, by learning the dynamics and the dimensionality reduction together, the Koopman Autoencoder learns a nonlinear latent-space representation of the state that implicitly results in better SSH predictions.

The advantages of using the Koopman Autoencoder over, for example, PCA-LIM are more apparent on daily timescales than on monthly timescales. In the North Pacific, prediction skill of the Koopman Autoencoder relative to PCA-DP on daily-averaged data is 4.5% higher than that of PCA-LIM but is only 3.0% higher for monthly-averaged data; in the North Atlantic, Koopman skill is 1.1% higher than PCA-LIM on daily data but is 1.3% *lower* on monthly data. One potential reason is that the assumptions underlying LIM may be better satisfied for monthly averages than daily averages, because monthly-averaged fields smooth out small-scale, nonlinear features (Sardeshmukh & Sura, 2009; Stephenson et al., 2004). The Koopman Autoencoders also outperform PCA-LIM by a wider margin in the North Pacific than in the North Atlantic. This may be because the inverse barometer component constitutes a larger share of SSH variability in the North Atlantic region (about 71% in the North Atlantic on daily timescales vs. 32% in the North Pacific; see Figure S3 in Supporting Information S1). This high-frequency variability may be well-represented by white noise, underpinning the relative success of PCA-LIM.

3.2. Sensitivity to the Number of Dimensions

Both the dimensionality reduction and learned propagator's predictions may be sensitive to the latent space dimensionality. Figure 3 explores both of these sensitivities. Due to the computational cost of training each network, sensitivity to dimensionality is examined only for daily-averaged North Pacific SSH, as the Koopman Autoencoder was shown to generate skillful predictions for these dynamics.

As shown in Figure 3a and Table S3 in Supporting Information S1, reconstruction performance improves as the latent space dimensionality is increased to $d = 40$ for all dimensionality reduction techniques. Just as in Section 3.1, for any given number of dimensions, the CAE has the best reconstructions, outperforming PCA by 2%–4%, while the Koopman Autoencoder has the worst reconstructions, with reconstruction MSE 1%–13% higher than that of PCA.

Like the reconstructions, the predictions of the Koopman Autoencoder also improve as the dimensionality increases (Figure 3b). This is implied by Koopman operator theory, which states that infinitely many observables must be prescribed to guarantee a nonlinear dynamical system is fully determined. Nevertheless, the utility of using the Koopman Autoencoder for building propagators diminishes as dimensionality increases. Figure 3c shows the domain-averaged prediction skill of the Koopman Autoencoder relative to PCA-LIM predictions using the same dimensionality. For all dimensionalities, the Koopman Autoencoder outperforms PCA-LIM forecasts up

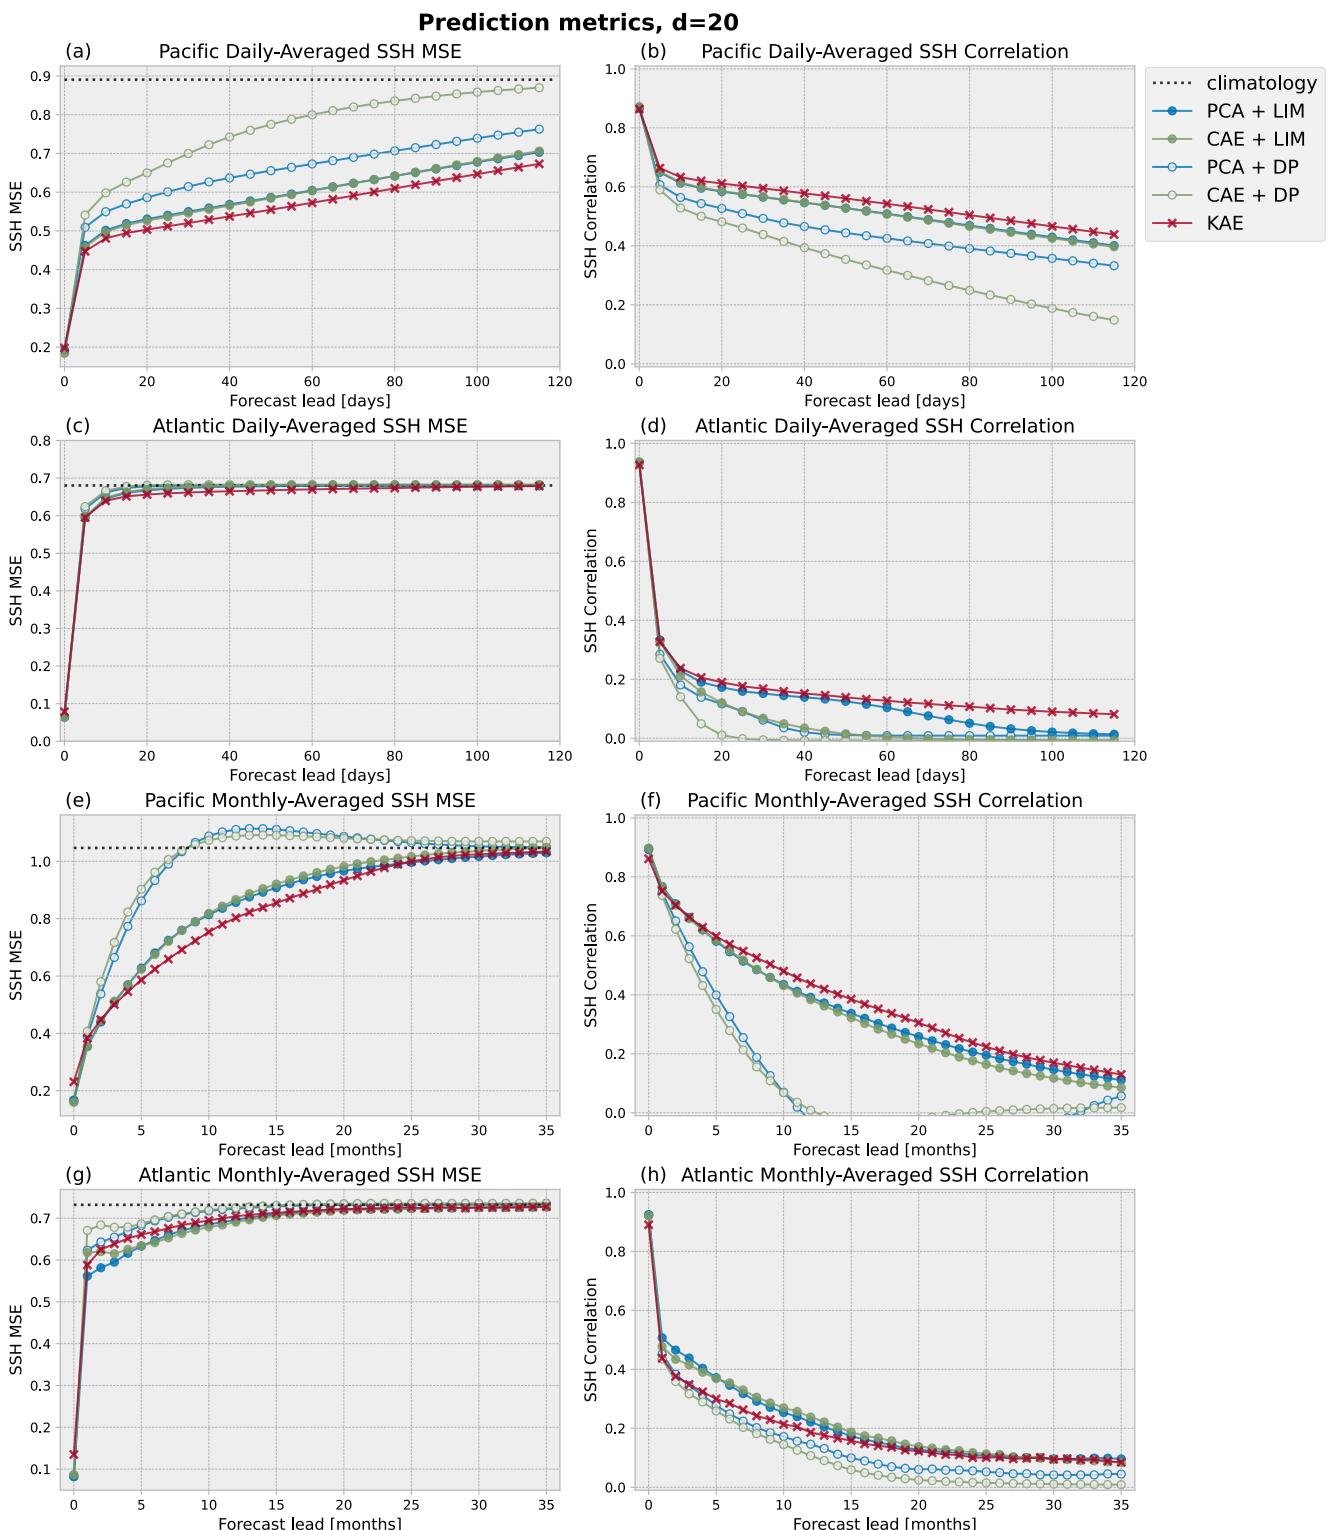

Figure 2. Forecast MSE and Pattern Correlation in the North Pacific and North Atlantic on daily and monthly timescales. Colors indicate dimensionality reduction techniques (red for the Koopman Autoencoder, blue for PCA, and light green for CAE), while markers indicate propagation techniques (x's for the Koopman Autoencoder, filled circles for LIM, and open circles for DP). The black dotted line indicates the climatological MSE of SSH.

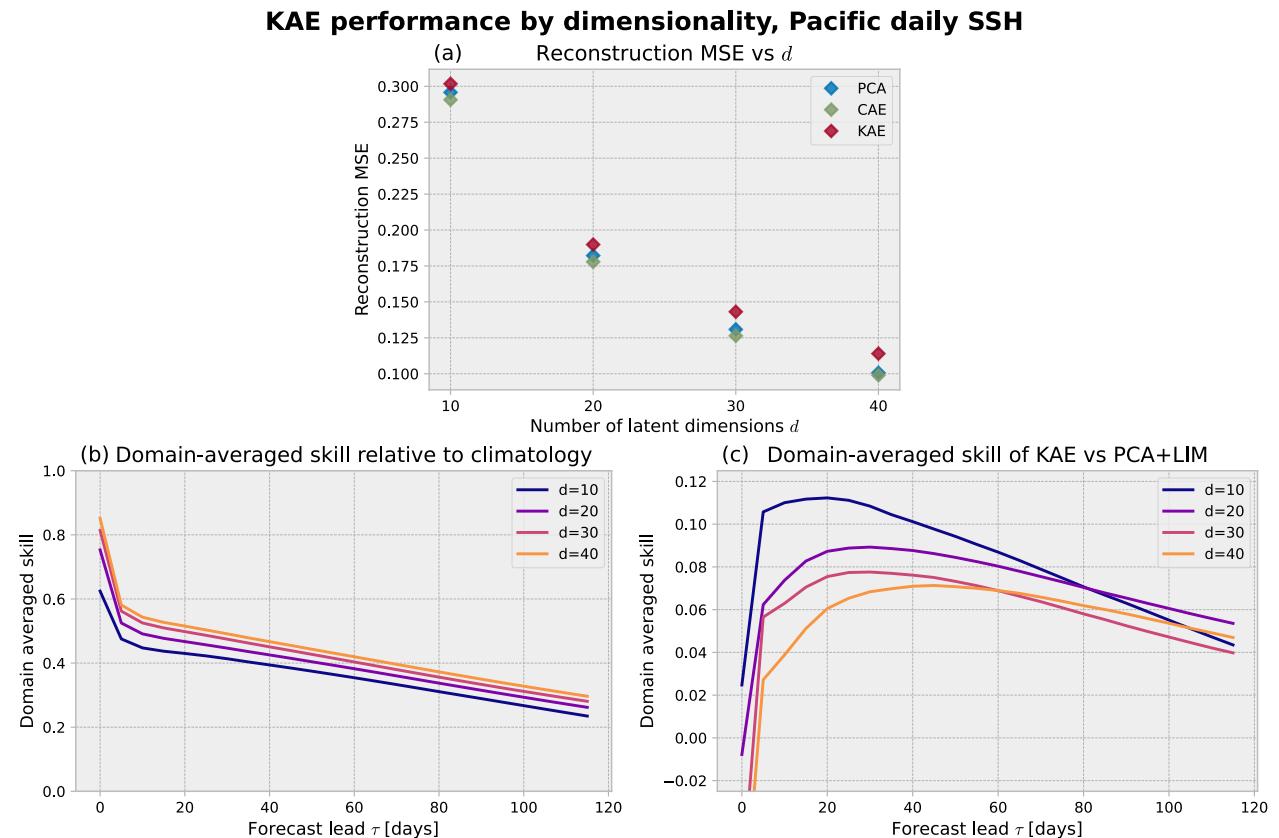

Figure 3. Sensitivity of the Koopman Autoencoder to dimensionality for predicting North Pacific daily-averaged SSH. (a) Reconstruction error by dimensionality for PCA (blue), CAE (light green), and the Koopman Autoencoder (red). (b) Domain-averaged MSE skill scores of the Koopman Autoencoder predictions relative to climatology for different latent space dimensionalities. (c) Domain-averaged skill score of the Koopman Autoencoder relative to equivalent dimensionality PCA-LIM for different forecast leads.

to $\tau = 120$ days; however, up to forecast leads of $\tau = 60$ days, skill of the Koopman Autoencoder decreases as the dimensionality increases. Much of this seems to be simply because the Koopman Autoencoder becomes worse at reconstructions relative to PCA for higher latent dimensionalities (e.g., 1% higher MSE for $d = 10$ vs. 13% higher MSE for $d = 40$; see Table S3 in Supporting Information S1). Thus, due to the challenges of optimizing autoencoders with higher-dimensional latent spaces, the Koopman Autoencoder approach may be most useful for developing low-dimensional forecasts.

3.3. Regions of Skill

To understand how the Koopman Autoencoder attains its performance, Figure 4 shows the MSE-skill score of the Koopman Autoencoder relative to PCA-based propagators for daily SSH forecasts in the North Pacific and North Atlantic. We focus on PCA-based propagators because of the simplicity and interpretability of linear, orthogonal dimensionality reduction. For example, due to the orthogonality of modes, applying damped persistence to the principal components results in purely local dampening of SSH at each location.

Figure 4a shows domain-averaged MSE skill scores for the Koopman Autoencoder and PCA-LIM relative to PCA-DP in the North Pacific. Skill scores for the Koopman Autoencoder and PCA-LIM relative to PCA-DP increase from about zero to a maximum at a lead of about 30 days, and gradually taper for longer-term forecasts. However, the Koopman Autoencoder skill is much higher than that of PCA-LIM at all lags—by 72% at lead 5 days and by at least 47% for leads up to 120 days.

Figures 4c–4e and 4f–4h show the regional variations of Koopman Autoencoder skill relative to PCA-DP and to PCA-LIM, respectively, for a few different lead times. Notably, the Koopman Autoencoder is better at reconstructing SSH than PCA at low latitudes but is worse at midlatitudes (Figure 4c). However, by lag $\tau = 5$ days, the

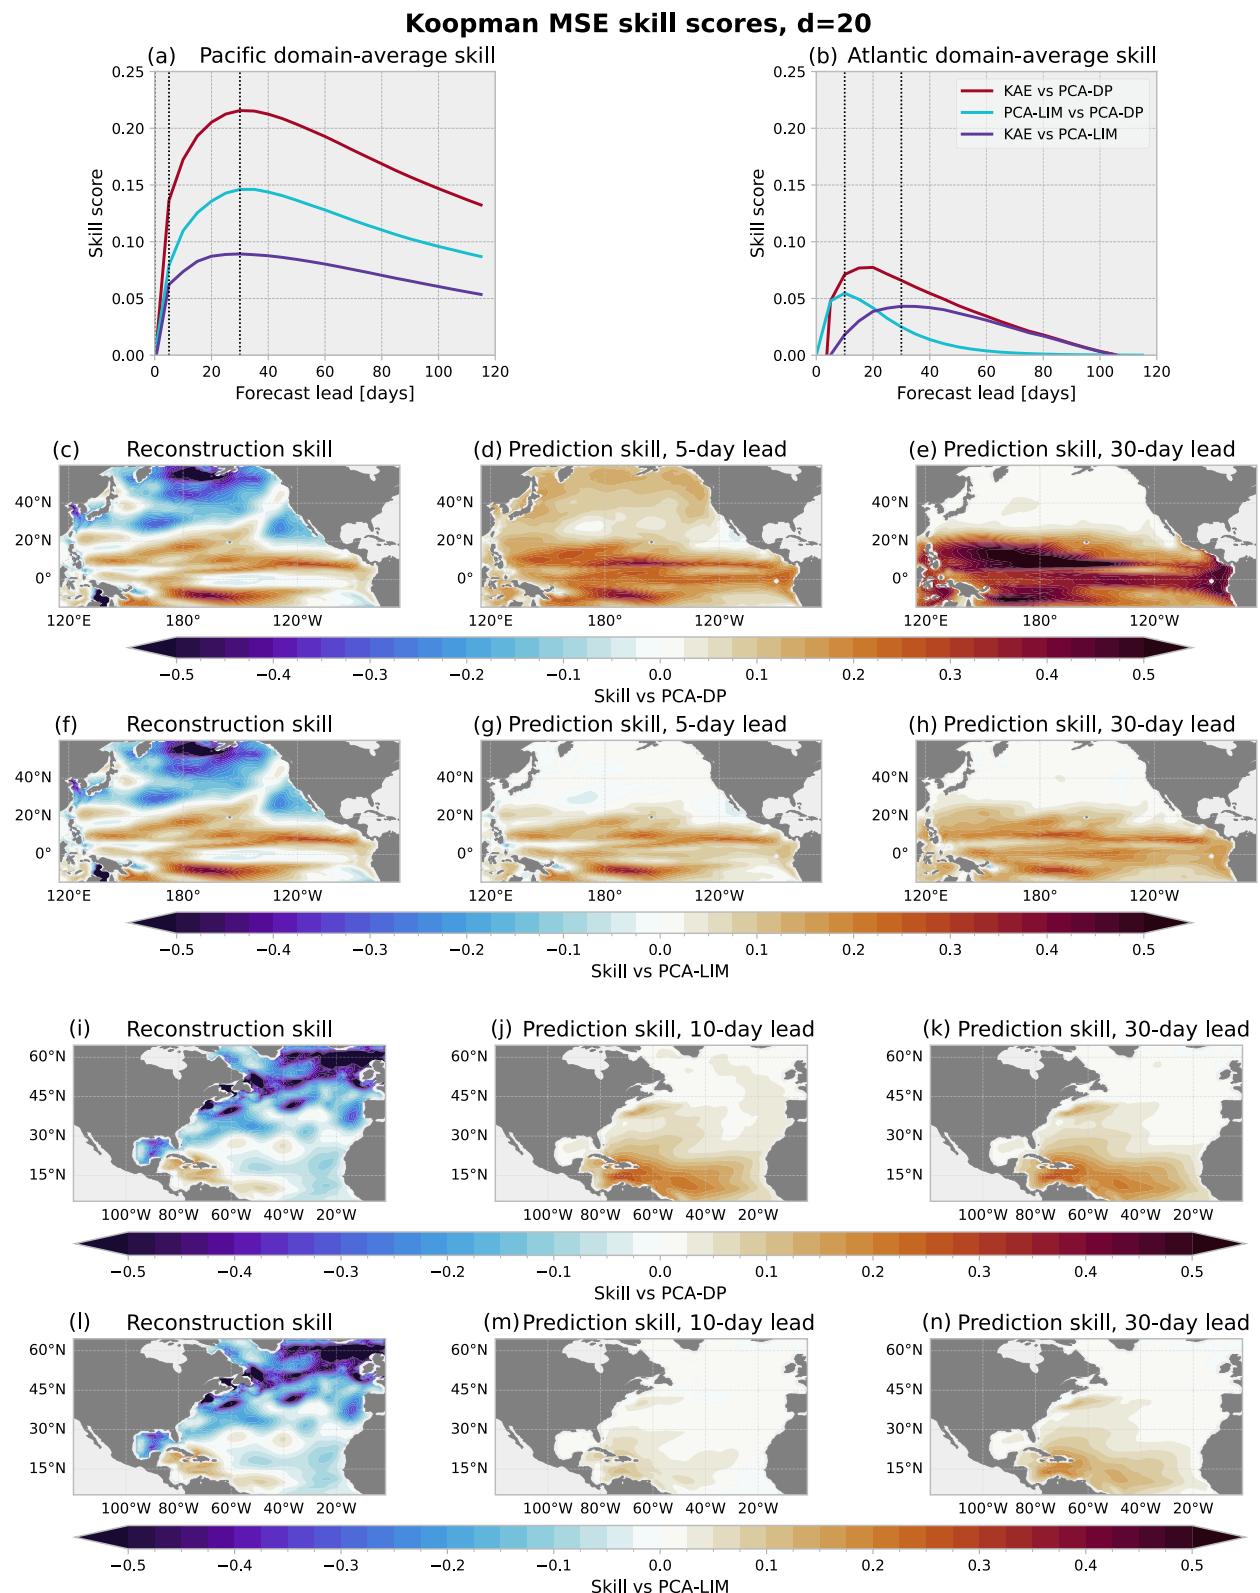

Figure 4. Koopman Autoencoder MSE skill scores for daily-averaged North Pacific (a, c–h) and North Atlantic (b, i–n) SSH predictions. (a, b): Domain-averaged skill as a function of lead time. Red: Skill of Koopman Autoencoder relative to PCA-DP. Purple: Koopman Autoencoder relative to PCA + LIM. Cyan: Skill of PCA-LIM relative to PCA-DP. Black dotted lines indicate forecast leads used for panels (c–h). (c, d, e, i, j, k): Skill scores of Koopman Autoencoder relative to PCA-DP at select time lags. (f, g, h, l, m, n): Same but for skill relative to PCA-LIM.

negative skill in the midlatitudes has diminished compared to PCA-LIM (Figure 4g), and there is positive skill relative to PCA-DP over the entire domain (Figure 4d). Because the midlatitude SSH variability is dominated by the high-frequency inverse-barometer component, midlatitude SSH dynamics are inherently less predictable than low-latitude dynamics. Therefore, for North Pacific regional-scale predictions, quality representations of SSH in the tropics are much more helpful for regional-scale predictions than representations in the midlatitudes. Because the Koopman Autoencoder learns dimensionality reduction and propagation together, it can deploy its latent dimensions to focus on representing low-latitude SSH initial conditions particularly well. In contrast, when the dimensionality reduction is done separately, dimensions may be wasted on characterizing variability that is not predictable.

The skill maps also highlight dynamics that the PCA-based propagators do not fully capture. For instance, since PCA-DP characterizes the *local* predictability of SSH, skill of the Koopman Autoencoder relative to PCA-DP indicates that it is capturing *nonlocal* drivers of SSH. Midlatitude skill in the Northeastern Pacific at leads of $\tau = 5$ days (Figure 4d) could come from sea level pressure anomalies advected by midlatitude Westerlies, which traverse the Pacific basin on $\mathcal{O}(5\text{--}10)$ days. In the low latitudes, the skill of the Koopman Autoencoder with respect to PCA-DP and PCA-LIM increases until about 30 days (Figure 4a), with the strongest skill occurring in narrow, zonal bands adjacent to the equator (Figure 4h). This timescale and region of enhanced skill is consistent with the timescale and westward propagation of Equatorial Rossby waves.

In the North Atlantic, reconstruction errors for the Koopman Autoencoder at time $\tau = 0$ are poor, with domain-average skill of -0.14 relative to the PCA reconstructions. However, once again, the latent space representation of the state results in better skill at nonzero time lags up to $\tau = 100$ days (Figure 4b). Figures 4i–4k show that prediction skill of the Koopman Autoencoder occurs primarily in the Atlantic Subtropical Gyre and Gulf Stream separation. Because gyre dynamics are associated primarily with low-variability geostrophic balance, such variability may be underrepresented in variance-targeting PCA-based reconstructions, although this variability may be predictable on the daily-to-seasonal timescale. Reconstruction skill relative to PCA suggests that the Caribbean Current may be a source of this gyre predictability for SSH predictions in the North Atlantic (Figure 4i).

4. Discussion

Statistical-dynamical models—and linear inverse models in particular—have become indispensable forecasting tools, owing to their simplicity, interpretability, and skill (Penland & Sardeshmukh, 1995; Alexander et al., 2008; von Storch et al., 1995). Modern techniques can help extract more information from data for nonlinear systems. Here, we trained convolutional neural networks with embedded time-stepping to learn a low-dimensional latent space that facilitates SSH prediction. Training the network to learn dimensionality reduction and propagation simultaneously tends to result in better forecasts than if the reduction and propagation are learned separately, as done typically with LIM for example.

We examined some sensitivities of the Koopman Autoencoder method compared to LIM. The skillfulness of the Koopman Autoencoder is most apparent in situations when the assumptions for LIM are least valid (such as on daily data, where the state vector includes highly nonlinear, small-scale features). Additionally, we examined the sensitivity to the dimensionality of the latent space. Our results suggest that the Koopman Autoencoder framework is best for building low-dimensional propagators; however, computational considerations led us to consider only one region and timescale and up to 40 latent dimensions, so the robustness of this result to different dynamics and a wider range of dimensionalities should be further investigated.

Spatial variations in the reconstruction skill of the Koopman Autoencoder point to sources of predictability that the Koopman Autoencoder leverages to outperform LIM. We identified tropical Pacific SSH as a source of predictability for North Pacific daily-averaged SSH and the Caribbean Current SSH for North Atlantic SSH. Although this study was limited to univariate fields, previous studies have demonstrated that including multiple variables can improve LIM predictions (Brennan et al., 2023; Capotondi et al., 2022; Newman, Alexander, & Scott, 2011). Using multiple input channels to incorporate different fields may improve the Koopman Autoencoder's SSH predictions and reveal additional sources of predictability.

The focus of this study has been to develop an efficient propagator for SSH and to assess its forecasting skill. The imposed linearity of the dynamics in the latent space could be relaxed to obtain better predictions. However,

the comprehensive theory underpinning linear systems makes the linear propagator potentially appealing for interpretation, yielding possible advantages in applications like predictability (Tziperman et al., 2008; Vimont et al., 2014), emulation (Beucler et al., 2021; Bi et al., 2023), and inference (Baldovin et al., 2020; Falasca et al., 2024).

One question is how the latent state can be physically interpreted (Behrens et al., 2022; Shamkh et al., 2023). Under Koopman operator theory, the latent space variables are observables of the dynamical system state, but the nonlinearities in the encoder and decoder make it challenging to interpret what these observables measure. One approach to gaining understanding of the latent space could be to probe the sensitivity of the decoder to changes in the latent space, either through observing the sensitivity of the outputs to latent space perturbations (Leeb et al., 2022; Oring et al., 2021) or examining the gradients of the decoder (Baehrens et al., 2010; Mamalakis et al., 2022). Such methods for interpreting the latent space, coupled with eigenanalysis for understanding the timescales for the propagator, could help elucidate the physical processes represented in the latent space, and is left for future work. Nevertheless, we believe this study has demonstrated a potentially useful approach for developing efficient, low-dimensional linear propagators for climate fields.

Data Availability Statement

The CESM2 Large Ensemble Data set is available from the NCAR Climate Data Gateway at <https://doi.org/10.26024/kgmp-c556> (Danabasoglu et al., 2021). The code used for data processing, training, analysis and visualization in this study, as well as the files for reproducing the software environment, are provided under the MIT license at https://github.com/andrewbrettin/koopman_autoencoders_ssh_prediction (Brettin, 2025). Figure 1 was built using the PlotNeuralNet software preserved at <https://doi.org/10.5281/zenodo.2526396>, which is available via the MIT license (HarisIqbal88, 2018).

Acknowledgments

AB is supported by the VoLo Foundation. LZ was supported by NOAA Grants NA20OAR4310411-T1-01 and NOAA-OAR-CPO-2019-2005530, 1148, by the KITP Program “Machine Learning and the Physics of Climate” under the National Science Foundation Grant NSF PHY-1748958 and by Schmidt Sciences, LLC. EAB is funded, in part, by NOAA Grants NA24OARX431C0022 and NA22OAR4310621. We acknowledge high-performance computing support provided by the NSF National Center for Atmospheric Research (NCAR) Computational and Information Systems Laboratory (CISL, 2023). We thank Aurora Basinski-Ferris, Adam Subel, and Chris Pedersen for numerous helpful discussions on this work. We thank the anonymous reviewers and the editor for their feedback, which helped improve the manuscript.
